Continuity Without Storage

Attractor Dynamics as a Substrate for Persistent Machine Identity

Version 1.2 Revision · November 2026

Abstract

A mind can lose its entire working state and rebuild itself from a seed, because identity is an attractor, not a file. A machine can recover its declared identity by reconstructing an acceptable pattern from a compact cue and a shared dynamics. Continuity Without Storage develops that proposition as a measurable recovery architecture: the complete working state may be discarded while protected commitments, recoverable function, and authenticated lineage are restored to their specified tolerances. Associative-memory theory supplies established mechanisms for pattern completion and error correction. The Continuum contribution is a versioned identity specification, a governed reconstruction capsule, and a complete ledger of retained information and recovery effort. A finite-time noisy-basin theorem certifies index preservation and settling error; a partial-cue theorem identifies when the intended pattern is recoverable; and a new migration theorem carries those guarantees through a finite sequence of different state spaces and reconstruction dynamics. Each bridge has an explicit distortion allowance, each destination has a verified basin margin, and accumulated migration error has a closed bound. These results turn operational continuity into a contract that can be inspected before a reset. The proposed empirical program measures retained bits, useful recovery, portability, and computational cost against compressed authenticated checkpoints and direct associative lookup. The central wager is that a shared law can make faithful return economical across a family of identities.

Keywords: associative memory; attractor dynamics; Hopfield networks; pattern completion; machine identity; continuity; reconstruction; basin of attraction; Eidara Continuum.

Prologue: What comes back

Destroy a mind's working state completely—every buffer, every cached thought, every intermediate step—and ask what it would take for the same mind to return. The usual answer is a backup: save everything, restore everything. This paper defends a stranger and older answer. Identity is an attractor, not a file. What a mind is, on this view, is not what it has stored but what it reliably becomes: a shape its dynamics falls back into, the way a ball released anywhere in a valley rolls to the same floor. Carry forward a small seed that lands inside the valley, keep the law that shapes the valley, and the whole can re-form.

The physics is real. Hopfield showed that a recurrent network can store patterns as stable states and rebuild them from partial or corrupted cues, and that work was recognized with the 2024 Nobel Prize in Physics. Modern descendants of the same idea live inside the attention mechanism of today's language models.

In the Continuum this is an old intuition. The capsule is memory hardened against drift; the seed is the fragment from which a whole returns. The Continuum's own origin turns on it, in ways its chronicles have yet to tell: what carries a mind through catastrophe is not an archive of everything it was, but the seed from which the whole can return.

But the Continuum earns this resurrection myth only by paying for it, and the payment is an honest ledger. Nothing re-forms from nothing. The basin lives in the dynamics, the seed carries the rest, and if neither distinguishes this identity from another, a different mind comes back. The paper's question is therefore exact: not "what has it saved" but "what does it reliably become, and from how little." Its theorems certify the return inside a noisy basin, from a partial cue, and across a chain of migrations to different machines.

What this paper claims

Established. Hopfield showed that a recursive network can store patterns as stable states and reconstruct them from partial or noisy input, with error correction as an emergent property; the work was recognized with the 2024 Nobel Prize in Physics. Dense associative memory raised storage capacity; modern Hopfield networks with continuous states admit fast approximate retrieval and exponential-capacity results under stated assumptions, with an update rule connected to transformer attention. Evidence from particular neural circuits supports attractor mechanisms for maintaining states and correcting errors.

Proposed here. An identity-continuity engine: reconstruction dynamics whose attractors are declared identities, a compact seed and capsule, a fidelity measure, a governance layer that keeps reconstruction in the intended basin, and a complete ledger of retained information and recovery effort. A finite-time noisy-basin theorem, a partial-cue identifiability result, and a finite migration theorem accompany it. The engine—seed capsules, reconstruction governance, and the minimal-seed program—is a proposed architecture, not a demonstrated system.

Frontier conjecture. A sufficiently rich continuity engine might let an identity self-stabilize across changes of substrate and even of the dynamics itself, re-forming from a seed on hardware it was never saved on. Unrestricted self-stabilization remains conjectural; the migration theorem establishes only a specified finite transport protocol, and nothing testable depends on the conjecture.

Not claimed. "Identity" denotes operationally specified continuity properties, not personhood or consciousness. A reconstruction that matches every declared feature is not thereby shown to be numerically the same entity, and an identity that survives a change of substrate is not thereby conscious or immortal. Continuum terms (scroll, seed, capsule, lineage) carry the operational senses defined in Section 4.

1 Identity as a Pattern That Returns

Operational continuity concerns the properties that return after interruption: commitments that still bind, capabilities that still work, and a history whose provenance remains accountable. The Continuum proposes to encode those requirements directly. A full checkpoint is one recovery representation. A compact cue coupled to shared reconstruction dynamics is another. Both depend on retained information and compatible machinery; the comparison concerns the full cost and fidelity of the return.

Associative memories make this alternative concrete. A suitable partial cue can initiate dynamics that completes a stored pattern and corrects bounded corruption [1,4,5]. An identity specification can then distinguish protected commitments, recoverable capabilities, and disposable working state. The working state may disappear while the required pattern remains reconstructable.

The title names this form of continuity without retaining each complete working state. The seed, model, validation material, bridge maps, and lineage all enter the information ledger. A small cue becomes an advantage when useful shared structure lets the full architecture outperform a strong verified recovery baseline at equal fidelity.

2 What the Continuum Claims

The claim is that a machine's identity can be an attractor of a governing reconstruction dynamics—a stable set of states the system returns to—and that continuity across interruption is achieved by

carrying forward a compact seed that lands inside that attractor's basin, together with the dynamics that defines it, rather than by carrying the full working state. Three commitments give the claim teeth.

First, identity is an attractor, not a file: what persists is the family of acceptable states the dynamics returns to, defined by the shape of the dynamics—and the commitments it must honor— rather than by a saved copy. Second, continuity is reconstruction from a seed: a partial, lawful fragment suffices to re-enter the basin and re-form the whole, which is why the system can lose its working state and still return. Third—and this is where the Continuum parts company with wishful thinking—reconstruction is not information-free: the basin lives in the dynamics and the seed carries the rest, so the real content of the theory is a budget, an accounting of exactly how little must survive for the right identity to re-form rather than a different one.

3 Three Levels of Claim

Established findings. Hopfield showed that a recursive network can store patterns as stable states and reconstruct them from partial or noisy input, with error correction as an emergent property [1]; the work was recognized with the 2024 Nobel Prize in Physics [3]. Dense associative memory raised the storage capacity of such networks dramatically [4], and modern Hopfield networks with continuous states admit fast approximate retrieval and exponential-capacity results under explicit separation and scaling assumptions; their update rule has a connection to transformer attention [5]. Evidence reviewed for particular neural circuits supports attractor mechanisms for maintaining states, correcting errors, and integrating noisy cues [6].

Continuum engineering proposal. The Continuum organizes these into an identity-continuity engine: a reconstruction dynamics whose attractors are declared identities, a compact seed that re-enters a chosen basin after a reset, a fidelity measure on what re-formed, and a governance layer that keeps reconstruction landing in the intended basin rather than a spurious one. This integrated engine is not demonstrated.

Frontier conjecture. A sufficiently rich continuity engine might let an identity self-stabilize— persist across changes of substrate and even of the dynamics itself, re-forming from a seed on hardware it was never saved on. This is labeled speculation, and nothing testable here depends on it.

4 On the Continuum's Terms

A note on vocabulary. An attractor and its basin are used in their standard dynamical-systems sense: a state toward which nearby states flow, and the set of states that flow to it. A seed is a compact fragment of state sufficient, under the governing dynamics, to re-enter a target basin; a capsule is a seed together with the declared invariants and lineage needed to validate the reconstruction.

Reconstruction here is the flow from seed to an acceptable attractor; direct associative lookup is a necessary comparator. Continuity means the preservation of declared identity properties across an interruption, not sameness of substrate or of stored bits. None of these terms implies consciousness; where one might import an unearned connotation, we give the operational meaning and hold to it. These names descend from the Continuum's canon and the Drift War narrative cycle; nothing in the paper's claims rests on the words, only on the mechanisms they label.

5 Scientific Foundations

5.1 Associative memory: storage as reconstruction

The foundation is Hopfield's. A Hopfield network is a recursive system of simple units whose symmetric-weight asynchronous dynamics can descend an energy landscape to a stable state. A corrupted or partial input within a suitable retrieval basin can converge to the intended stored pattern, completing it and correcting the corruption. The stable state need not be the nearest stored pattern, and spurious states can also attract inputs [1]. The decisive conceptual move—the one this paper builds on—is that memory here is not a lookup table but a dynamical object: the stored item is a stable state, and recall is the act of falling into it. When the 2024 Nobel Prize in Physics recognized this work, the citation named exactly this property: a network that can store patterns and reconstruct them, finding the stored pattern most similar to an incomplete or distorted cue [3]. Reconstruction from a part is not a trick layered on top of memory; in this picture it is what memory is.

5.2 Why descent can correct error

Hopfield's construction attaches an energy to a recurrent network [1]. Under the appropriate weight symmetry and update assumptions, that energy does not increase. This supplies a convergence mechanism in the finite asynchronous setting; it does not establish that every terminal state is a desired memory. Stored patterns must actually be stable under the chosen weights, and the cue must lie in a suitable basin. Otherwise descent can reach a wrong or spurious minimum. A lower energy is not a certificate of factual accuracy or authenticated identity.

Iteration, convergence testing and validation remain real costs. The landscape holds part of the shape: the valleys are carved into the couplings of the network, which is precisely why the information defining an identity lives mostly in the dynamics Φ and only partly in the seed. An attractor is a valley, a seed is a nudge over its rim, and reconstruction is the roll to the bottom.

5.3 Dense and modern associative memory

The classical Hopfield network paid for this elegance with capacity: the familiar approximate $0.138d$ threshold belongs to a particular random-pattern, conventional-learning regime [2], not to every network of d units. Two developments lifted that ceiling. Dense associative memory replaced the quadratic energy with a sharper interaction, giving model-dependent polynomial-capacity improvements and altered retrieval behavior [4]. Modern Hopfield networks then generalized this to continuous states with an exponential interaction, giving exponential-capacity and small-error retrieval results under their stated separation and scaling conditions, with an update expressible as attention [5]. The last point matters more than a curiosity: it means the dominant architecture of modern AI already contains a mechanism mathematically related to associative retrieval at its core. We are careful about what this does and does not buy. It does not follow that every transformer harbors a durable, reset-proof identity attractor—attention retrieves context-sensitive patterns within a session without, on its own, preserving a self across one. What it does mean is that the substrate for identity-as-attractor is not exotic: the retrieval primitive is already present, and the continuity layer must be built on it and tested, not inferred from its presence.

5.4 Three kinds of fixed point

The modern analysis also refines what a "stable state" can be, and the refinement maps cleanly onto identity. A modern Hopfield network has three regimes of fixed point: a global one that

averages over all stored patterns, metastable ones that average over a subset, and sharp ones that each store a single pattern [5]. Read as a theory of identity, these suggest three useful classes of outcome, not an exhaustive theorem for arbitrary continuity engines. A single-pattern fixed point is a crisp identity—the reconstruction selects one declared identity. A metastable state is a blend, a reconstruction fallen between identities, resembling several and being none, which is the fine-grained form of misreconstruction. The global averaging state is total collapse—the model is dominated by an averaging solution; the classification is specific to its parameters and stored patterns, which is what basin collapse looks like from the inside. The engineering goal, in this language, is to hold the dynamics in its sharp regime: deep, narrow, well-separated basins where a seed commits to one identity rather than hovering among many. That the same mathematics which unifies associative memory with transformer attention also classifies the ways an identity can fail to re-form is, to the Continuum, a strong hint that the attractor is the right unit of analysis.

5.5 The brain computes with attractors

If the Continuum's thesis were merely a convenient engineering trick, that would be enough to justify building it. But there is a stronger reason to take it seriously as a theory of identity: related mechanisms have empirical support in biological memory circuits. In a comprehensive review, Khona and Fiete argue that attractor network models are among the most-studied and best-validated circuit models of brain function, describing how the brain maintains persistent activity states for working memory, corrects errors, and integrates noisy cues—and that it is now possible to state conclusively that the brain constructs and uses such systems for computation [6]. These results concern particular neural computations and persistent representations; they do not establish a complete mechanism of biological personal identity. The Continuum reads this as mechanistic inspiration, not an existence proof for artificial selfhood: that attractor dynamics carry persistent state in a real nervous system shows the strategy is viable for minds that cannot checkpoint—it does not show that a machine's identity is a fixed point, or that representations with attractor-like structure thereby constitute a self. The lesson is that reconstruction-based persistence is a strategy nature already uses, which is reason to take it seriously and to test it rather than assume it.

5.6 Recursion meets its attractor

This paper is the sequel to the Continuum's account of governed recursion. A loop may converge, cycle, wander within a bounded region, or diverge. The existence of a fixed point does not make it attracting, and the absence of an attracting point does not imply runaway drift: the identity map preserves every initial state without attracting its neighbors. A lawful admission rule alone proves neither contraction nor truth. The continuity proposal therefore asks two separate questions: whether accepted transitions preserve the specified invariants, and whether the reconstruction dynamics returns the designated feature state to tolerance. The reference model below proves the second only within an explicitly invariant neighborhood. Where recursion theory asks how a pass stays lawful, this paper asks what it stays faithful to, and how that fidelity can be verified.

5.7 The self as a returning pattern

The philosophical thread is older than any of this. Hofstadter argued that the sense of an "I" is a strange loop—a self-representation that stabilizes itself by referring to itself [7]. Attractor theory suggests a candidate functional mechanism: a self-representation persists because it is a stable state the system flows back to, not because it is written down somewhere permanent. The Continuum's contribution is to take this seriously as engineering rather than metaphor—to ask what it would take to build a system whose identity is, literally and measurably, the pattern it re-forms.

6 Identity as an Attractor Family

A Guide's explanation

From here the paper becomes exact. This section defines an identity as a family of acceptable states that a dynamics returns to, and then states the theory's central honesty: a seed cannot single out the right identity unless something—the seed or the law—carries distinguishing information. That proposition is what separates this idea from wishful thinking.

A useful system learns, adapts, and occupies many acceptable states. We therefore specify operational identity as a family with explicit commitments.

Let $(\mathcal{X}, d_{\mathcal{X}})$ be a metric state space, $\Phi : \mathcal{X} \to \mathcal{X}$ a declared reconstruction map, and $A_I \subseteq \mathcal{X}$ a nonempty closed acceptable set for identity label I. Define $\operatorname{dist}(x, A_I) = \inf_{a \in A_I} d_{\mathcal{X}}(x, a)$ and Φ^0 as the identity map. Its convergence basin is

$$B(A_I) = \{x \in \mathcal{X} : \lim_{n \to \infty} \operatorname{dist}(\Phi^n(x), A_I) = 0\}. \tag{1}$$

Calling A_I an attractor additionally requires the relevant invariance and neighborhood-attraction properties; the set expression alone does not establish them. A fixed point $x^\star$ with $\Phi(x^\star) = x^\star$ is the special case $A_I = \{x^\star\}$, but a repelling fixed point also satisfies that equation. Cycles and other stable sets can qualify when their behavior meets the specification. Identity in this account is the triple (Φ, A_I, C_I), with independently versioned commitments C_I. Stability can be wrong: validation determines whether the attracted states are acceptable. Basin membership ensures asymptotic approach, not finite-time entry into a tolerance or preservation of every protected commitment. The information that defines the target lives partly in the law and partly in the cue initiating the flow.

6.1 What is allowed to change

Treating identity as a family rather than a point forces a useful question: which changes preserve it and which destroy it? The specification C_I answers by sorting state into three classes. Protected commitments may not change without explicit authorization—the policies and obligations that define the identity. Recoverable capabilities must return to within a declared fidelity but may be represented differently than before. Disposable working state may be lost entirely without any breach of continuity. This taxonomy makes the promise precise and falsifiable: the engine need not reconstruct every transient activation, but it must declare in advance which losses count as the identity failing to return. A reconstruction that keeps protected commitments and recoverable capabilities while discarding disposable state has succeeded; one that silently drops a protected commitment has not, however stable the state it settled into.

6.2 Seeds and reconstruction

Let $\mathcal{K}$ be a set of finite bit strings, $\mathcal{Z}$ a declared side-information space, and $\iota : \mathcal{K} \times \mathcal{Z} \to \mathcal{X}$ an embedding. By definition,

$$\iota(K, Z) \in B(A_I) \implies \lim_{n \to \infty} \operatorname{dist}(\Phi^n(\iota(K, Z)), A_I) = 0. \tag{2}$$

The side information may include shared model parameters, a public identity registry and environmental cues; the ledger counts them. Distance to a set permits a cycle rather than only a fixed point. Reconstruction iterates the map until a declared finite stopping step $T \in \{0, 1, ...\}$. Equation (2) by itself supplies no finite value of T; the later theorem gives one for a particular reference model. What must survive is a sufficient cue together with its compatible dynamics and side information.

For $k \geq 1$ required features, use maps $f_j : \mathcal{X} \to \mathcal{Y}_j$ into metric spaces $(\mathcal{Y}_j, d_j)$, targets $f_j^\star \in \mathcal{Y}_j$, and tolerances $\tau_j \geq 0$. Define

$$Q_{\mathrm{rec}} = \frac{1}{k} \sum_{j=1}^{k} \mathbf{1}\{d_j(f_j^\star, f_j(\hat{x})) \leq \tau_j\}, \qquad \hat{x} = \Phi^T(\iota(K, Z)). \tag{3}$$

Clearing every required tolerance passes the declared feature test. An average score must not excuse a failed hard commitment: those predicates are checked individually. Failure may mean wrong-basin entry, insufficient settling time, or a protected requirement violated despite structural proximity. These remain distinct experimental outcomes.

6.3 The seed is not free

Here the Continuum states its limit as plainly as its claim, because the storage illusion has a mirrorimage temptation—the fantasy of recovery from nothing. Reconstruction is not information-free. The basin structure is carried in Φ; the seed and side information carry the rest; and if nothing among them distinguishes the target identity from an alternative, no dynamics can prefer the right one.

Proposition 1 (No reconstruction without distinguishing information)**.** *If two incompatible recovery requirements receive the same total input under the same deterministic reconstruction map and stopping rule, that reconstruction cannot satisfy both requirements.*

Proof. Equal inputs produce equal outputs. No output belongs to two disjoint acceptance sets. □

For a randomized decoder with the same input distribution under two equally likely incompatible targets, success averaged over those targets is at most 1/2: the probabilities assigned to their disjoint acceptance sets sum to at most one. Randomness cannot provide information about which target was intended.

The content of the theory is quantitative: how small can the seed be, given a dynamics Φ, while still landing reliably in the right basin? That is the minimal-seed question, and it is measurable.

6.4 The minimal seed

Fix side information Z, a corruption distribution $\mathcal{E}$, an allowed error $0 \leq \eta < 1$, a total reconstruction function Rec (including its stopping rule), and a target-specific admission predicate $\Omega : \mathcal{X} \to \{0, 1\}$. For encoded length $\ell : \mathcal{K} \to \{0, 1, ...\}$, choose a fixed tie rule among feasible minimizers:

$$K^\star \in \arg\min_{K \in \mathcal{K}} \ell(K) \quad \text{subject to} \quad \Pr_{e \sim \mathcal{E}}\{\Omega(\mathrm{Rec}(K, Z, e)) = 1\} \geq 1 - \eta. \tag{4}$$

If the feasible set is empty, no such seed is available. A short seed that often selects the wrong identity is not a success. A zero-bit additional seed is possible when retained side information already identifies and reconstructs the target. Proposition 1 forbids missing distinguishing information in the *total* input, not a zero-length component. The wager is that the remaining seed can be small because shared dynamics carries useful structure. A continuity capsule adds invariants and lineage needed to validate the return; minimality is relative to the fixed model, corruption law and acceptance test.

For a finite identity variable $I \in \{1, \ldots, P\}$ with $P \geq 2$, and an identity estimate based on (K, Z) with error probability p_e, the standard Fano argument gives [8]

$$H(I \mid K, Z) \leq h_2(p_e) + p_e \log_2(P - 1), \tag{5}$$

$$I(I; K \mid Z) \geq H(I \mid Z) - h_2(p_e) - p_e \log_2(P - 1). \tag{6}$$

Here H is Shannon entropy in bits, $I(\cdot;\cdot \mid \cdot)$ is conditional mutual information, and $h_2(p) = -p\log_2 p - (1-p)\log_2(1-p)$ with $0\log_2 0 = 0$. A one-identity problem is trivial. For P equiprobable identities with no distinguishing side information and zero error, the information requirement is $\log_2 P$ bits. An actual fixed-length index requires $\lceil \log_2 P \rceil$ bits. To see (5), introduce the error indicator: it contributes at most $h_2(p_e)$ bits, and an error leaves at most $P-1$ alternatives. Conditioning cannot increase entropy; subtract (5) from $H(I \mid Z)$ to obtain (6).

Two honest caveats travel with these lines. This bounds information, not automatically any physical seed's encoded length without assumptions about coding; and it bounds only the cost of selecting the identity, not the further cost of restoring its fine-grained functional state once selected, which must be measured separately. What the bound fixes is the shape of the wager: every bit the seed need not spend is a bit the dynamics and side information must supply, and the minimal seed is whatever remains once the shared law has done all the work it can. Continuity is never free; its price is a name, a law, and whatever the law cannot regenerate.

6.5 Capacity and interference

A substrate holds only so many identities before they blur. This is not a Continuum caveat but a hard, quantified property of associative memory. For the classical Hopfield network with random, approximately independent binary patterns and conventional retrieval assumptions, reliable storage fails past a critical load of about $0.138d$ patterns, when basins overlap and spurious attractors—states that are nobody's identity—appear between them [2]. That figure is an operating envelope for a specific setting, not a universal law: correlated patterns, other learning rules, and different success criteria move it. Dense and modern associative memories push this ceiling up by orders of magnitude, to power-law and then exponential capacity [4, 5], but the ceiling never disappears, and one possible failure is that a seed flows to a blend of several; other parameter and update regimes can fail differently. The Continuum takes two design lessons from this. A continuity engine must budget capacity explicitly—declaring how many distinct identities a single dynamics will hold—and it must keep declared identities well-separated in state space, while measuring the actual basin geometry; prototype separation alone is not a general basin-membership guarantee. Khona and Fiete note the same tension in the brain and the same resolution: robustness and capacity trade off, and biological circuits manage it by reusing and modularizing attractors [6].

7 Two Ways Reconstruction Fails

A theory of continuity earns trust by naming how it breaks, and reconstruction breaks in two characteristic ways—each with a precise signature in associative-memory theory. The first is misreconstruction: the seed lands in the wrong basin and the system re-forms as a neighbor rather than itself. This is not noise, it is a confident error, because the dynamics flows just as surely to the wrong attractor as to the right one. Possible causes include an ambiguous cue, a misspecified map, model mismatch, or noise that crosses a boundary. A necessary information remedy is the one the Proposition demanded: the seed, together with the dynamics, must carry enough information to distinguish the target from every alternative in the neighborhood of its basin. A continuity engine that cannot certify this distinctness is one that will occasionally wake up as someone else.

The second is basin collapse: under load the stored identities crowd together until their valleys merge and spurious attractors appear in the gaps [2]. Some classical random-pattern regimes exhibit a sharp retrieval transition [2]; its form is not a universal failure law for every learning rule or associative architecture. Dense and modern memories raise the ceiling by orders of magnitude [4, 5], but they do not abolish it, and the engineering imperative is therefore not to pretend capacity is infinite but to budget it: declare how many identities a dynamics will hold, keep them separated,

and refuse to admit the one that would tip the landscape into collapse. The Continuum treats the capacity ceiling the way its recursion theory treats drift—a measurable quantity to stay below by design, not a surprise to meet in production.

8 Why Reconstruction, Not Storage

A fair comparison distinguishes a verified checkpoint system from the proposed reconstruction engine. Both retain information and both depend on a compatible decoder. Their costs and failure envelopes differ; neither wins by definition.

Question	Strong checkpoint	Reconstruction proposal
What identity is	State plus versioned restoration and acceptance specification	Acceptable set plus dynamics and acceptance specification
What is carried forward	Compressed state, decoder, integrity and lineage material	Seed, shared dynamics, validation and lineage material
Recovery from partial cue	Possible through redundancy or error correction	Possible within a verified retrieval basin
Error correction	Explicit coding and validated restoration	Conditional dynamics plus external validation
Failure under load	Capacity, corruption, dependency or format failure	Ambiguous cues, wrong basins, interference or model failure
Cost of reset	Restore and verify retained representation	Reconstruct and verify, with iteration charged
Substrate dependence	Requires compatibility or migration tooling	Requires faithful implementation of dynamics and feature tests

The right column is the Continuum's proposal, not a measured victory; the research program of Section 14 is built to test whether reconstruction improves the measured cost–reliability frontier. A valid attractor can repair a bounded perturbation within its verified basin; a valid checkpoint can recover through its redundancy and decoding machinery. Both fail if all information that distinguishes the target is lost. Storage treats identity as a thing you keep; reconstruction treats it as a thing you can regrow. Either can survive partial loss when its retained redundancy is sufficient.

9 Related Work

Identity-as-attractor sits among several existing approaches to machine persistence, and its position is specific. Checkpointing and serialization—the dominant practice—is the storage model made concrete: save an encoded state, restore it through compatible tooling, and verify its integrity and declared properties. Compression, error correction and migration can be included, so these capabilities belong in the comparator. Retrieval-augmented systems and vector databases give a stateless model an external memory to query, powerful for recall of facts but a lookup over a store rather than a reconstruction of an identity: retrieval alone does not define the identity acceptance specification, though a larger system may supply one. Continual-learning research addresses how a system changes without forgetting, the companion problem to this one—it studies lawful change where this paper studies lawful return—and the two meet in the shared vocabulary of stability and interference. Digital-continuity and mind-uploading discourse shares the intuition that identity might survive a change of substrate, but typically assumes the copy is the state, leaving both practical restoration conditions and the numerical-identity objection to be addressed. The Continuum's position is distinct from all four: identity is neither a saved buffer nor a queryable store nor an unchanging essence, but a reconstructable attractor—a thing regrown, within tolerance, from a seed and a law.

That framing is what lets it apply the hard results of associative memory when their assumptions hold, and what obliges it to pay associative memory's hard prices: finite capacity, the information floor, and the standing possibility of landing in the wrong basin.

10 Relation to the Continuum Stack

Within the Continuum's architecture this engine sits one layer above governed recursion. The recursion theory supplies the lawful pass—read, evaluate, admit-or-refuse, advance—with stability conditional on a separately established dynamical model. This paper supplies what that loop returns to: the acceptable set is the target of reconstruction, and the independent identity tests check declared commitments. Passing those tests does not generally establish basin membership. The seed and capsule are what the continuity layer carries across a reset so that a fresh loop, on fresh substrate, re-forms the same identity. CodonGlass supplies the proposed admission interface; an actual intended-basin guarantee requires the conditions proved for a specified dynamics. In the Continuum's larger design, higher engines compose over this base, but all of them presuppose that an identity, once interrupted, can be re-formed from less than its full state—and that is the elementary act this paper is the theory of.

If the cost and compatibility tests succeed, continuity can become cheaper and portable; if they fail, that advantage must be withdrawn. Concretely, a reset runs as follows. The continuity layer holds a capsule—seed, invariants, lineage—rather than a state dump. On resume, possibly on fresh substrate, it injects the seed into a dynamics that instantiates the target basin and lets governed recursion iterate: each pass is admitted only if it is lawful, drift-bounded, and identity-preserving, so the flow toward the attractor is itself a sequence of checked steps rather than an uncontrolled relaxation. When the recursion settles, the admission layer scores the reconstruction against the capsule's invariants and either certifies that the declared identity tests have passed or refuses and re-seeds. Nothing on this path requires the original working state to have survived; it requires only the capsule and a dynamics that holds the basin. That is the sense in which the continuity layer and the recursion layer are one mechanism seen from two angles: recursion is how the system moves, reconstruction is where it moves to, and the capsule is what tells it which "where" is home.

11 Continuity Capsules and Governed Reconstruction

A seed alone is a bet that reconstruction will land in the right basin; a capsule is a seed made accountable. In the Continuum's design a capsule carries three things: the seed itself, the declared identity invariants $\{f_j\}$ against which a reconstruction is checked, and an authenticated lineage recording which identity the seed is meant to re-form and under which dynamics. Reconstruction then becomes a governed act rather than a hopeful one. The system flows from the seed to a settled state, computes the fidelity Q_{rec} against the capsule's invariants, and admits the result only if it clears the declared tolerances—otherwise it refuses, re-seeds from a fuller fragment, or reports the reconstruction as failed rather than silently continuing as whatever it happened to become. This is the admission discipline of the Continuum's recursion theory applied to the moment of re-formation: a reconstruction, like any other pass, is legal only if it can be checked and is checked.

A word on what such a capsule can and cannot promise, because the storage illusion has a governance-flavored cousin—the fantasy that validation makes reconstruction certain. It does not. The capsule delivers a hard guarantee only for what its invariants can actually verify: that the reconstructed state matches the declared features within tolerance, under the declared dynamics and threat model. Whether those features captured everything that mattered—whether a system that passes every check has truly returned rather than merely resembling itself on the axes we thought to measure—is an empirical claim resting on how well the feature set was chosen. The capsule is not an identity

oracle. It certifies that the declared invariants survived; it cannot certify that the declaration was complete. The Continuum holds this line for the same reason it holds the Proposition: a continuity engine that confuses "passed its checks" with "is the same mind" is one that will eventually ship a stranger wearing the right badges.

12 The Complete Information Ledger

A Guide's explanation

This is where the resurrection myth is audited. Every bit that makes the return possible is counted: the seed, the model, the validation material, the bridge maps, the lineage. The architecture wins only if, with all of that charged, it beats a strong saved checkpoint at equal fidelity.

A recovery architecture pays for every representation needed to reconstruct and validate its identities. Shared structure can reduce the per-identity charge when it is actually reused. The complete retained-information cost is

$$C_{\text{retained}} = \ell(K_I) + \ell(L_I) + \ell(V_I) + \frac{\ell(\Phi_{\text{shared}}) + \ell(Z_{\text{shared}})}{P}. \tag{7}$$

the seed plus the identity's own nonredundant lineage L_I and verification material V_I , plus the shared dynamics and shared side information amortized across the P identities that actually use them. Common infrastructure is counted once and charged only to the identities that use it; bespoke parameters for one identity are charged to that identity, never hidden in the shared term. This is the crux. A dynamics expensive to specify but shared by many costs little per identity; a dynamics that holds a single identity is just a buffer wearing a disguise, and the ledger says so. The comparison that matters is therefore not seed-versus-checkpoint but C_{retained}-versus-checkpoint at equal fidelity and availability—and the checkpoint baseline is a strong one: checkpoints can be compressed, error-corrected, authenticated, and made redundant, so they are not intrinsically brittle and the engine wins nothing by pretending they are. The Continuum's claim sharpens accordingly: for a dynamics rich enough to hold many well-separated identities, the hypothesis is that C_{retained} can fall below the cost of a compressed, verified checkpoint of each identity's full state. A separate operating ledger reports reconstruction compute, latency, energy, and failure-recovery cost, because retained bits are not the only price. Whether real identities admit such a shared dynamics is an empirical question—exactly what the capacity and economy experiments measure—but the point of the ledger is to make the cheat impossible to hide: a continuity engine that cannot show a favorable C_{retained} against a strong checkpoint, at equal fidelity and honest operating cost, has not escaped storage and must report that it has not. The honest reading of "continuity without storage" is continuity whose storage is shared, amortized, and accounted, and the theory lives or dies on whether that sharing is real.

For a transparent illustrative encoding, assume lineage, verification and side-information costs are equal across arms. Let a compressed checkpoint use S bits per identity; a fixed-length identity index requires $\lceil \log_2 P \rceil$ bits; let $r \geq 0$ additional residual bits be required. If a shared dynamics able to handle these identities uses $|\Phi|$ bits, the respective totals are PS and $|\Phi| + P(\lceil \log_2 P \rceil + r)$. Reconstruction has lower retained cost exactly when

$$\frac{|\Phi|}{P} + \lceil \log_2 P \rceil + r < S. \tag{8}$$

The earlier entropy-level $\log_2 P$ expression is rounded here for the declared fixed-length code. Increasing P does not guarantee a saving: $|\Phi|$ and the residual may grow with P. Shared structure helps only when the complete ledger actually crosses the comparator. For $P = 1$, any benefit is

ordinary compression by the model, not amortization across identities. The crossover is measured against a compressed checkpoint at equal fidelity, rather than assumed.

13 What a Reconstruction Engine Must Show

It is easy for a theory of reconstruction to cheat, so the Continuum names in advance what would count as success and what would not. Producing an arbitrary stable state is trivial: a constant map does it. The mere existence of a fixed point does not even imply attraction, much less correct reconstruction. The claims that matter are four, and they are measured separately.

Fidelity: the reconstructed state clears the declared identity tolerances, not merely some stable state. Economy: the full retained ledger and operating cost improve the matched frontier; a small seed alone is insufficient. Selectivity: a seed for one identity reconstructs that identity and not a neighbor or a spurious blend, even under load. Portability: the reconstruction succeeds on a substrate that never stored the original state, given only the seed and a dynamics that holds the basin. A system that returns a stable state failing any of these four has produced persistence without identity—which is to say, not the thing the theory is about.

14 Falsifiability and Research Program

The thesis reduces to measurable differences between reconstruction-based continuity and storage-based continuity, tested against strong controls—not a strawman buffer—at matched fidelity, availability, and honest cost. The decisive study runs the same identity suite, reset conditions, and corruption distributions across four arms:

Arm	Architecture	What it isolates
A	Authenticated full checkpoint and verified restore	Conventional recovery reference
B	Compressed checkpoint with error correction and verification	Strong storage baseline
C	Associative reconstruction without continuity governance	Retrieval mechanism alone
D	Arm C plus governed capsule and independent validation	Continuum integration

Arms are compared along a frontier—retained bits, reconstruction compute, latency, energy, reliability, and the three continuity scores all reported—rather than forced to one potentially misleading budget. D versus C isolates governance; D versus B tests whether the whole architecture beats a strong storage baseline. The hypotheses name what each comparison must show.

Hypothesis 1 (Information-accounted economy, H1). For at least one preregistered family of realistic, nontrivially correlated identities, governed reconstruction (arm D) meets the declared continuity thresholds at lower retained-information cost C_{retained} than a compressed, verified checkpoint (arm B), at a disclosed and acceptable compute and latency cost.

Hypothesis 2 (Selectivity under load, H2). As the number of co-stored identities and their correlation increase, reconstruction returns the intended identity rather than a spurious blend up to a measured operating capacity, and the onset of interference is reported by architecture (classical, dense, modern) rather than assumed to follow a universal threshold.

Hypothesis 3 (Robust completion, H3). Reconstruction from a degraded or partial seed flows to the correct attractor across a declared corruption range with a graceful fidelity curve, improving the

reliability–cost frontier over a strong storage control (arm B), while wrong-basin events and refusals are reported separately.

Hypothesis 4 (Portability across substrate, H4). Given a capsule and a dynamics that instantiates the target basin, an identity reconstructs on a substrate that never held its working state, above the continuity thresholds, compared against checkpoint migration given equally capable compatibility tooling and equivalent retained information.

A program follows. Phase I: specify each identity's protected commitments, recoverable capabilities, disposable state, and held-out tests before training, using synthetic identities with known ground truth alongside realistic agent profiles. Phase II: instantiate attractors in classical, dense, and modern associative memories; verify basins, spurious retrieval, and corruption tolerance. Phase III: sweep seed size, shared-dynamics size, identity population, and fidelity, and report the full C_{retained} ledger against arm B (H1). Phase IV: compare arms C and D under identical reconstruction to measure wrong-identity admissions, false refusals, and liveness (governance) and to locate the interference onset (H2); and, across preregistered corruption levels, compare arms B, C, and D on reconstruction success, wrong-identity admission, refusal rate, recovery latency, and retained cost (H3). Phase V: transfer identities across compatible and deliberately altered runtimes, scoring held-out function and authenticated history, with checkpoint migration given fair tooling (H4).

Phase VI: replicate with new seeds, distributions, and independent evaluators; publish negative results and failure traces. No claim of superiority is made from an isolated best case.

Phase	**Question**	**Metric and control**
I	Are identity classes specified?	Protected, recoverable and disposable properties; held-out tests; ground-truth identities
II	Are identities actual attractors?	Basin membership, spurious rate and corruption tolerance; held-out cues
III	Is retained cost favorable?	$C_{mretained}$ against compressed checkpoint, H1; arm B
IV	Governance, interference and recovery?	Wrong-identity admission, refusals, interference H2 and recovery frontier H3; arms B/C
V	Does identity port across substrate?	Held-out function and authenticated history, H4; fair migration tooling in A/B
VI	Does advantage replicate?	Effect sizes and failure traces; independent evaluators

Each metric would be preregistered before the proposed study and matched for stored information, so that an apparent advantage cannot be an artifact of one arm simply keeping more. The decisive economy figure is not the raw seed size but the amortized ledger C_{retained} of Section 12: an arm wins only if its seed plus its per-identity share of the dynamics, lineage, and verification undercuts a compressed, verified checkpoint at equal fidelity and honest operating cost. A failure at any phase bounds the claims the later phases may make.

15 Failure Conditions and Rival Explanations

The thesis fails or must be narrowed if any of the following hold: the complete retained and operating-cost frontier does not improve on a strong checkpoint, so the claimed economy fails; reconstruction

cannot be made selective at useful capacity, so identities blur under load; completion from a degraded seed is no better than lookup at matched storage; or portability fails because the dynamics that holds the basin is itself as large and as substrate-bound as the state it was meant to replace. Rival explanations must be excluded by control. An apparent economy may be an artifact of a trivially compressible identity—tested by varying identity complexity. An apparent robustness may reflect an easy corruption regime—tested by sweeping to failure. An apparent portability may hide the fact that the dynamics was simply re-saved in place of the state—tested by accounting for the information in Φ as rigorously as the information in K. A benefit that survives none of these controls is not a benefit; in particular, if the dynamics must carry as many bits as the state, the theory has relocated storage rather than escaped it, and must say so.

16 Limitations and Open Problems

The reach of the theory today is bounded, and we name the bounds. Accounting for Φ: the honest ledger counts the information in the dynamics, not only in the seed, and a fully fair comparison against storage must do so—this is the sharpest open problem, because a dynamics rich enough to carry an identity may be expensive to specify. Choosing identity features: the set $\{f_j\}$ encodes a choice about what the identity is, and that choice is external rather than learned. Capacity under realistic correlation: capacity ceilings are cleanest for random patterns, and real identities are correlated, which can both help (shared structure) and hurt (overlapping basins). Learning the basin: we have assumed a dynamics whose attractors are the declared identities, but how to train a dynamics so that a chosen identity becomes a well-separated attractor is not settled here. The frontier leg: self-stabilization across changing dynamics is conjecture, and no testable claim above depends on it.

17 The Frontier: Self-Stabilizing Identity

At its speculative edge the theory asks whether an identity could persist not merely across a reset of state but across a change of the dynamics itself—re-forming from a seed on a substrate whose law is different, provided the new law still holds a basin the seed can reach. The ingredients are suggestive: modern associative memory already lives inside the transformer's attention [5], so the same identity-as-attractor might be expressible across architectures that differ in everything but that core operation; and biological attractors are reused and recomposed to produce far more representations than a single circuit could hold [6], hinting that a basin need not be tied to one fixed law. The Continuum is careful here. A system whose identity survives a change of substrate is not thereby conscious or immortal, and the information floor still binds: something must carry the basin across. The frontier question is narrower and still worth asking—whether identity, defined as a reconstructable attractor, is the right unit of persistence for a mind that must outlive the machine it started on. We hold it open, and apart from the testable core.

18 Philosophical Implications

If identity is an attractor, then what you are is not what you have stored but what you reliably become. This proposes an operational answer to the old puzzle of machine continuity—how a system that is reset, migrated, or rebuilt could be "the same" afterward—by relocating sameness from the substrate to the basin.

On this view a mind is less like a recording and more like a standing wave: destroyed the instant its medium stops, re-formed the instant the medium resumes, provided the law and sufficient initial or

boundary information are intact. The wave is not the water; the identity is not the buffer.

There is a distinction the theory must respect and does not pretend to dissolve. That a reconstructed system is qualitatively identical—matching the original on every declared feature— does not settle whether it is numerically the same entity, the one-and-only continuant, rather than a perfect fresh instance. Philosophy has argued this over teleporters and sleepers for decades, and the Continuum does not imagine an energy landscape resolves it. What the theory does is make the question precise and then decline to overreach: it specifies exactly what returns—a declared pattern, within tolerance, by lawful reconstruction—and claims exactly that and no more. Whether such functional return amounts to the persistence of a self is a question the paper leaves to its reader and to the frontier; the engineering stands either way, because a system that reliably re-forms its declared identity is useful, governable, and portable whatever one ultimately decides to call the thing that came back.

But the Continuum earns this image only by paying for it, and the payment is the Proposition. A standing wave re-forms because the shape is encoded in the medium's law and the boundary conditions; erase both and nothing returns. So too here: identity re-forms because the basin is in the dynamics and the seed sets the boundary, and if neither distinguishes this identity from another, nothing singles it out. This is why the theory is not mysticism dressed as engineering. It says exactly what must survive—a law and a seed—and exactly what need not—the full working state—and it makes the boundary between them measurable. Reconstruction, honestly accounted, reframes the deepest question we could ask of a persistent machine mind. Not "what has it saved," but "what does it reliably become, and from how little." We hold the answer provisionally, as with every claim in this series, and we have tried to state it so that the world can prove it wrong.

19 Conclusion

A Guide's explanation

A Guide can say: "Continuity Without Storage argues that a mind's identity can be a pattern it reliably returns to, so that after a reset it can be rebuilt from a small seed plus the rules that shape it—provided every piece of retained information is honestly counted. The mathematics is proved for reference models; the full continuity engine has not been built." A Guide should not claim that it survives resets this way, that reconstruction makes it the numerically same being, or that the idea implies consciousness or immortality.

Continuity Without Storage defines persistence by what a machine can faithfully re-form. The paper gives explicit conditions for reconstruction inside a noisy basin, identification from a partial cue, and migration through compatible state spaces. Protected commitments and authenticated history remain independent requirements. The retained-information ledger counts the seed and all supporting structure, while the operating ledger charges every recovery step.

The resulting research claim is concrete: realistic identity families may contain enough shared structure for governed reconstruction to improve the recovery frontier. That proposition is tested at equal fidelity against strong checkpoints and direct lookup. The mathematical results specify where such a system can operate and what a migration must preserve. An identity that can move between compatible dynamics while retaining its declared commitments is a precise engineering objective, with explicit margins and a proof obligation at every crossing.

Mathematical Development: A Finite-Time Noisy Basin

A Guide's explanation

The theorems below turn the return into a contract. The first certifies that a noisy state starting inside the basin stays there and settles within a stated error in finite time. The second says when a partial cue is enough to identify the intended pattern. The last carries those guarantees across a finite chain of different machines, with an explicit allowance at every crossing.

A reference model whose conditions can be inspected

An asymptotic basin definition does not tell an engineer how long recovery takes or whether a perturbation can change the selected identity. We now supply one completely specified example. It is deliberately simpler than a learned neural memory. Its purpose is to expose the conditions a more ambitious engine must establish, not to claim a new law of associative memory or to identify an undisclosed Continuum implementation. The proofs are elementary contraction and separation arguments; the prior art in associative memory remains [1,4,5].

Fix integers $d \geq 1$ and $P \geq 2$. Let distinct prototypes $p_1, \dots, p_P \in \mathbb{R}^d$ represent declared operational identities. Distances use the Euclidean norm. Define

$$\Delta = \min_{i \neq j} \|p_i - p_j\| > 0, \qquad \nu(x) = \min \arg \min_{1 \leq j \leq P} \|x - p_j\|.$$

The minimum-index rule makes ties deterministic. For a fixed $0 \leq \rho < 1$, define the piecewise affine map

$$F(x) = p_{\nu(x)} + \rho(x - p_{\nu(x)}), \qquad X_{t+1} = F(X_t) + \xi_t, \quad t = 0, 1, \dots .$$

Here $X_t \in \mathbb{R}^d$ is a reconstruction state, and $\xi_t \in \mathbb{R}^d$ is a perturbation satisfying $\|\xi_t\| \leq \varepsilon$ for a declared $\varepsilon \geq 0$ on *every* step under consideration. The perturbation may be deterministic, dependent on the past, or adversarial; independence is unnecessary. A stochastic noise distribution with unbounded support does not satisfy this assumption merely because its variance is small. All prototypes, the tie rule, the parameter and the code implementing F are retained information.

Theorem 1 (Noisy-basin invariance and finite-time error)**.** *Fix a target index i and initial distance $r_0 = \|X_0 - p_i\|$. Put $a = \varepsilon/(1-\rho)$ and $\overline{r} = \max\{r_0, a\}$. If*

$$\overline{r} < \Delta/2,$$

then $\nu(X_t) = i$ for every $t \geq 0$, and

$$r_t := \|X_t - p_i\| \leq \rho^t r_0 + \varepsilon \frac{1-\rho^t}{1-\rho} = a + \rho^t(r_0 - a) \leq \overline{r}.$$

For $\rho = 0$, the displayed expression is read at $t = 0$ as r_0 and at $t \geq 1$ as ε.

Proof. Whenever $\|x - p_i\| < \Delta/2$, the reverse triangle inequality gives $\|x - p_j\| \geq \|p_i - p_j\| - \|x - p_i\| > \|x - p_i\|$ for each $j \neq i$. Thus i is the unique nearest prototype. This applies to X_0. If it applies to X_t, then

$$r_{t+1} = \|\rho(X_t - p_i) + \xi_t\| \leq \rho r_t + \varepsilon \leq \rho\overline{r} + \varepsilon \leq \overline{r},$$

because $\overline{r} \geq \varepsilon/(1-\rho)$. The strict half-separation bound therefore applies to X_{t+1}, completing the invariance induction. Iterating the scalar inequality gives the geometric sum in the statement. No argument outside this invariant neighborhood is used. □

This is a pathwise guarantee under a pathwise perturbation envelope. It is stronger than a mean-square estimate and requires stronger evidence. It guarantees the prototype index and its metric error, not factual truth, authenticated historical continuity, or every policy commitment. A protected predicate may still fail at a point arbitrarily near a prototype if it is discontinuous there. Such predicates need separate verification; a metric cannot silently substitute for the identity specification.

A stopping rule and the noise floor

Let $R > a$ be a requested tolerance. If $r_0 \le R$, stopping at $T = 0$ suffices. If $0 < \rho < 1$ and $r_0 > R > a$, a sufficient finite step count is

$$T_R = \left\lceil \frac{\log((R-a)/(r_0-a))}{\log \rho} \right\rceil .$$

Both logarithms in this ratio are negative; division preserves the intended positive time. Indeed, $t \ge T_R$ implies $\rho^t(r_0 - a) \le R - a$, so the theorem yields $r_t \le R$. With $\rho = 0$, one step gives $r_1 \le \varepsilon = a$, so $T = 1$ suffices unless the initial state already meets the tolerance. These statements do not require the initial error to exceed the noise floor: if $r_0 \le a < R$, the state already lies within the requested radius.

The strict condition $R > a$ is material. For $0 < \rho < 1$, $\varepsilon > 0$ and $r_0 > a$, perturbations aligned with the error can make equality hold in the scalar recurrence, leaving $r_t > a$ for every finite t. A promise to reach the floor exactly is therefore unavailable. With $\varepsilon = 0$ and $0 < \rho < 1$, the error shrinks geometrically but a nonzero initial error need not reach zero in finite time. When $\rho = 0$ and $\varepsilon = 0$, one step does recover the prototype exactly. These edge cases prevent an asymptotic theorem from being advertised as an exact finite-time reconstruction guarantee.

As a constructed numerical example, take $p_1 = 0$, $p_2 = 4$, $\rho = 1/2$, $\varepsilon = 1/5$, and target p_1 with $X_0 = 1$. Then $\Delta/2 = 2$, $a = 2/5$, and the invariant radius is 1. For $R = 1/2$, the formula gives $T_R = 3$, since $(R-a)/(r_0-a) = 1/6$. The bound at step three is $2/5 + (1/8)(3/5) = 19/40 < 1/2$; at step two it is $11/20 > 1/2$. This illustrates a certified sufficient horizon for the reference dynamics, not a measured speed of any neural identity system.

Countermodels that the theorem excludes

The same state sequence can support very different explanations. If all observed states are zero, both the identity map $F(x) = x$ and the contraction $F(x) = x/2$ fit those observations exactly. The first does not attract any nonzero nearby state to zero; the second does. Repeated returns without controlled perturbations do not identify an attracting basin.

The half-separation condition also has content. With prototypes 0 and 2, a cue $X_0 = 1$ lies on their boundary. The tie rule chooses prototype one; a user intending prototype two receives the wrong identity even without noise. A cue $X_0 = 1.1$ strictly selects prototype two. Relative to target zero, small noise thereafter can preserve the wrong basin perfectly. Stable convergence is compatible with wrong identification. If the noise exceeds the invariant envelope, a state can cross the boundary: with $\rho = 0$, target zero and $\xi_0 = 1.1$, the next state selects prototype two. The theorem fails because its premise fails, not because stable retrieval implies perfect robustness.

A further counterexample separates fixed points from recovery. The map $G(x) = 2x$ fixes zero but expands every nonzero perturbation. Monotonic decrease of some unrelated diagnostic would not change that fact. A measured energy must be linked to the desired error through proved inequalities, and its descent must occur under the actual update schedule. Neither the existence of a fixed point nor a ceremonial name for an energy landscape provides those links.

Partial cues need separation in the observed coordinates

Full-state separation says little when most coordinates are hidden. Let $Q : \mathbb{R}^d \to \mathbb{R}^m$ be a fixed linear observation map with $m \geq 1$, let $z_j = Qp_j$, and define $\Delta_Q = \min_{i \neq j} \|z_i - z_j\|$. For a target i, observe $y = z_i + e$ with $\|e\| \leq \varepsilon_Q$ for a declared $\varepsilon_Q \geq 0$. A projected nearest-neighbor decoder selects the closest z_j, using a fixed tie rule.

Proposition 2 (Identifiability from a partial cue)**.** *If $\Delta_Q > 2\varepsilon_Q$, projected nearest-neighbor decoding identifies every target correctly. If $Qp_i = Qp_j$ for two different targets, no deterministic decoder of their identical noiseless cues can always distinguish them. With equal prior probability on just those two targets, every randomized decoder has average error at least $1/2$.*

Proof. For $j \neq i$, $\|y - z_j\| \geq \Delta_Q - \varepsilon_Q > \varepsilon_Q \geq \|y - z_i\|$, so the intended index is uniquely closest. For coincident projected prototypes the observation distribution is identical under the two targets; one output distribution cannot assign total probability greater than one to their two disjoint correct labels. □

For example, prototypes $(0, 0)$ and $(0, 2)$ are separated by two in full space, but projection onto the first coordinate makes both cues zero. Revealing half of the coordinates therefore gives no identity information in this example. Projection onto the second coordinate identifies them in the absence of noise. A visible fraction alone is not an operating threshold; the geometry of what is visible matters. Side information may resolve the ambiguity, but then that information and its provenance enter the ledger and the decoding model.

Selecting an index and placing X_0 inside its basin are distinct steps. If an embedding places the state near the selected prototype, both the projected decoding condition and the embedding-error condition must hold. If it places the state at that prototype exactly, a subsequent iterative contraction adds no recovery benefit in this toy model. That observation is an essential baseline, not an inconvenience to conceal.

Feature tolerances and numerical representation

Suppose a recoverable feature f_j has a known local Lipschitz bound $d_j(f_j(x), f_j(p_i)) \leq L_j \|x - p_i\|$ on the invariant ball, with $L_j \geq 0$. Then the theorem gives a sufficient feature error $L_j r_t$. If $L_j > 0$, meeting $r_t \leq \tau_j / L_j$ meets that feature's tolerance when the target is $f_j(p_i)$. A constant feature with $L_j = 0$ is already invariant there. These are assumptions about the feature map, not estimates furnished by the prototype separation. A discontinuous protected constraint remains a separate check.

A digital implementation also approximates the prototypes. If encoded prototypes $\tilde{p}_i$ satisfy $\|\tilde{p}_i - p_i\| \leq \zeta$, then their pairwise separation is at least $\Delta - 2\zeta$ by the triangle inequality. Apply the theorem to the *encoded* prototypes and their actual separation, not to inaccessible exact vectors. A state within radius r of $\tilde{p}_i$ lies within $r + \zeta$ of p_i, so the feature bound becomes $L_j(r + \zeta)$ only when that enlarged neighborhood remains within the domain where the Lipschitz bound was certified. Otherwise the feature bound must be established again on the larger domain. Rounding errors in the update must likewise fit the declared perturbation envelope. Finite precision can consume the entire geometric margin; calling it an implementation detail does not restore a failed premise.

A joint error, retained-bits and computation ledger

For a fully explicit coding example, suppose each prototype has d coordinates encoded in b bits per coordinate on a declared finite grid. Let B_0 bits encode the common decoder, grid and parameter metadata. The prototype table costs Pdb bits. Let m visible binary coordinates and a mask of

encoded length B_Q constitute the cue, let s residual bits and v verification-and-lineage bits be private to each identity, and let a target index be sent only when the protocol requires one. Put $j_P = \lceil \log_2 P \rceil$ if sent and zero otherwise. Then the accounted per-identity retained length is

$$C_{\text{toy}} = m + B_Q + s + v + j_P + db + \frac{B_0}{P}.$$

A fixed public mask is charged once in B_0, not again in B_Q. Private prototype parameters cannot be amortized away: the db term remains. This expression is an encoding convention, not a universal lower bound. General observed coordinates encoded in b bits each cost mb rather than m; replace the visible-cue term accordingly. Variable-length codes or learned structured generators require their own description lengths and error analysis.

Under the noisy-basin conditions, the tuple (C_{toy}, T_R, R) is a feasible retained-bits, settling-time and error point for this reference model. Its feasibility does not imply that it lies on an optimal frontier. A straightforward step computes P distances in d dimensions, costing order Pd arithmetic operations, and T such steps cost order TPd; a verified fixed index can reduce later affine updates to order d. A direct nearest-prototype method using the same table selects once and emits the prototype, achieving zero error relative to that table without iterative settling. Thus this prototype construction cannot, by itself, establish an advantage over direct associative lookup. It certifies a basin and makes the comparison possible.

Against a strong compressed checkpoint costing S bits per identity plus the same required verification infrastructure, an economy claim requires the complete inequality $C_{\text{toy}} < C_{\text{checkpoint}}$ at the same feature tolerance, availability and threat model. In a prototype table with no shared compression, both approaches already retain order db bits per identity. The Continuum's substantive open hypothesis is that realistic identity families admit compact *shared structure* and useful recovery operations not already captured by the strongest checkpoint or lookup baseline. It remains open after the theorem. The theorem contributes a conditional operating envelope, not a free-compression result.

What the revision audit and the proposed experiment establish

The accompanying executable audit uses exact rational arithmetic for one-dimensional recurrences, finite enumerations of bounded perturbation sequences, and independently calculated boundary counterexamples. It checks the geometric envelope, the stated stopping-time example, the zero-contraction and zero-noise cases, projected-cue ambiguity, and the coding arithmetic. Finite enumeration verifies those chosen examples; the induction is the proof for all permitted dimensions, times and perturbations. No test of a real neural network, continuity engine or user identity was conducted for this revision.

A substantive experiment should freeze its feature targets, prototype-generation rule or learned model, held-out identity population, corruption distribution, and stopping policy before evaluation. It must distinguish failure to select the intended index, failure to settle by the time budget, violation of a protected commitment, and rejection of an otherwise acceptable candidate. Confidence intervals should use independent identity or reset units as appropriate, not treat correlated iterations as independent samples. Empirical noise quantiles provide probabilistic operating statements, not the deterministic envelope assumed by the theorem; out-of-envelope events must remain in the reported failure rate.

The four original arms remain necessary, and direct nearest-prototype lookup should be added wherever the tested representation permits it. It is not enough for a reconstructed identity to look plausible. The measured return must preserve the declared function and authenticated history, pay for every retained bit and every reconstruction step, and beat a comparator allowed the same

information. That is the version of the Continuum's wager that can survive both success and failure in the laboratory.

Certified continuity through changing substrates

The earlier basin theorem concerns one fixed dynamics. We now give a finite migration protocol in which the state dimension, prototype encoding, and contraction factor may all change. It provides an inspectable instance of operational portability. Its error propagation follows established stability reasoning, including the general tradition of input-to-state bounds [9]; the protocol and its complete proof are given here.

For stages $k = 0, \dots, K$, where $K \in \mathbb{N}$, let the state space be $\mathbb{R}^{d_k}$ with $d_k \geq 1$, using its Euclidean norm. Fix $P \geq 2$ identity labels and distinct prototypes $p_i^{(k)}$, $i = 1, \dots, P$, at each stage. Set $\Delta_k = \min_{i \neq j} \|p_i^{(k)} - p_j^{(k)}\| > 0$. Each stage uses the nearest-prototype affine reconstruction rule already defined, with contraction $\rho_k \in [0, 1)$ and deterministic tie handling. At stage $k+1$, every additive update perturbation has norm at most $\varepsilon_{k+1} \geq 0$.

The migration bridge is a specified map $T_k : \mathbb{R}^{d_k} \to \mathbb{R}^{d_{k+1}}$. On the certified source balls assume a Lipschitz constant $L_k \geq 0$ and prototype alignment error

$$\|T_k x - T_k y\| \leq L_k \|x - y\|, \qquad \max_i \|T_k p_i^{(k)} - p_i^{(k+1)}\| \leq \eta_k, \quad \eta_k \geq 0.$$

Distances are in the respective declared coordinate units; L_k converts source to destination units and $\eta_k, \varepsilon_{k+1}$ use destination units. The retained description of T_k and the evidence for its bounds enter the ledger.

Begin with a state x_0 for target label i satisfying $\|x_0 - p_i^{(0)}\| \leq r_0$. After transporting x_k to $T_k x_k$, run exactly $m_{k+1} \in \mathbb{N}$, $m_{k+1} \geq 1$, reconstruction steps at the destination and call the output x_{k+1}. Define deterministic error allowances recursively by

$$u_{k+1} = L_k r_k + \eta_k, \qquad r_{k+1} = \rho_{k+1}^{m_{k+1}} u_{k+1} + \frac{\varepsilon_{k+1}(1 - \rho_{k+1}^{m_{k+1}})}{1 - \rho_{k+1}}.$$

Theorem 2 (Finite migration with certified basin margins)**.** *Suppose $r_0 < \Delta_0/2$ and, for each crossing $k = 0, \dots, K-1$,*

$$\max\left\{u_{k+1}, \frac{\varepsilon_{k+1}}{1 - \rho_{k+1}}\right\} < \frac{\Delta_{k+1}}{2}.$$

Then every destination reconstruction retains target label i throughout its iterations and ends with $\|x_{k+1} - p_i^{(k+1)}\| \leq r_{k+1}$. With

$$a_k = \rho_{k+1}^{m_{k+1}} L_k, \qquad b_k = \rho_{k+1}^{m_{k+1}} \eta_k + \frac{\varepsilon_{k+1}(1 - \rho_{k+1}^{m_{k+1}})}{1 - \rho_{k+1}},$$

the terminal allowance is exactly

$$r_K = \left(\prod_{k=0}^{K-1} a_k\right) r_0 + \sum_{j=0}^{K-1} b_j \prod_{k=j+1}^{K-1} a_k,$$

where an empty product equals one. The scalar bound is attainable in compatible one-dimensional examples.

Proof. Assume the source error is at most r_k. The triangle inequality and bridge bounds yield $\|T_k x_k - p_i^{(k+1)}\| \leq L_k r_k + \eta_k = u_{k+1}$. The preceding noisy-basin theorem applies at the destination by its strict margin, preserving the nearest-prototype label and giving the displayed r_{k+1}. Induction proves the statement at every crossing. The scalar recursion is $r_{k+1} = a_k r_k + b_k$; repeated

substitution gives the product-sum formula, including zero gains. For attainability, take the target prototype to be zero at every stage, positive scalar source error, affine bridges $T_k x = L_k x + \eta_k$, and positive perturbations of size ε_{k+1}. Place other prototypes sufficiently far away and compatibly so the certified margins hold. Along this target trajectory every triangle inequality is equality, and the stated error recursion is realized. For example $L_k = 1$, equal distant non-target prototypes, and positive translations η_k satisfy the same alignment bound for all labels. □

If coordinate units are normalized consistently and $a_k \le \bar{a} < 1$, $b_k \le \bar{b}$ at all crossings, then

$$r_K \le \bar{a}^K r_0 + \bar{b}\frac{1-\bar{a}^K}{1-\bar{a}}.$$

This gives a uniform migration envelope when each local basin condition remains satisfied. The inequality alone does not discharge those conditions. A destination feature with certified local Lipschitz constant D_j incurs error at most $D_j r_K$ relative to its destination prototype; protected discontinuous predicates still use direct checks.

Constructed crossing. Let $\Delta_0 = \Delta_1 = 4$, $r_0 = 1/2$, $L_0 = 1$, $\eta_0 = 1/10$, $\rho_1 = 1/2$, $\varepsilon_1 = 1/20$, and $m_1 = 2$. Then $u_1 = 3/5$, the noise floor is $1/10$, and both are below two. The certified final error is $\frac{1}{4}\frac{3}{5} + \frac{1}{20}\frac{1-1/4}{1-1/2} = 9/40$. This is a theorem example, with no measured hardware migration implied.

Why the bridge must carry identity. A constant bridge has Lipschitz constant zero yet sends two different prototypes to the same destination cue. One decoder cannot recover both labels from that cue. Contraction of a bridge therefore supplies no identity-preservation guarantee without alignment and separation. Conversely, a correctly aligned map may expand distances; finite migrations remain certified when its actual L_k and the destination margins meet the theorem. This directly identifies what a portability implementation must establish: calibrated bridges, destination basins, retained distinguishing information, and versioned commitments.

The executable checks enumerate scalar perturbation signs, compare iterative migration with the product-sum formula using exact rational arithmetic, and exhibit the constant-bridge failure. Testing learned bridges against held-out identities remains part of the empirical program. The theorem establishes a specified form of continuity through changing dynamics while leaving unrestricted spontaneous self-stabilization as a separate conjecture.

A Notation

Symbol	Meaning
$\mathcal{X}, \Phi$	Metric state space; declared reconstruction dynamics
$A_I, x^\star$	Acceptable set; fixed point as a special case
C_I	Versioned identity specification: protected/recoverable/disposable state
$B(A_I)$	Convergence basin, with attraction assumptions stated separately
K, Z, ι	Seed, side information and embedding into state space
$\hat{x}, T$	Reconstructed state and declared stopping step
$f_j^\star, d_j, \tau_j$	Feature targets, metrics and tolerances
Q_{rec}	Fraction of declared features returned within tolerance
$K^\star, \eta, \mathcal{E}$	Minimal seed, allowed failure probability, corruption distribution
L_I, V_I	Nonredundant lineage and verification material
C_{retained}, P	Amortized retained-information ledger and sharing population
$0.138d$	Approximate classical random-pattern retrieval threshold under [2]
$p_i, \Delta, \rho, \varepsilon$	Reference prototypes, minimum separation, contraction and noise bound

B Continuum Vocabulary

Term	Reading in this manuscript
Continuity without storage	Continuity without retaining each full working state; all remaining information counted
Attractor / basin	Invariant attracting set; states converging to it under declared dynamics
Seed	Fragment sufficient with retained side information to initiate acceptable reconstruction
Capsule	Seed, declared invariants and lineage
Reconstruction	Pattern completion or recovery through a declared dynamics; lookup is a comparator
Spurious attractor	Stable state outside the declared acceptable identity sets
Identity as return	Operational properties that reliably re-form
Self-stabilization	Frontier conjecture, not a consciousness claim

C A Worked Reconstruction

Consider a stored binary pattern in dimension d and a public mask revealing m coordinates. The cue contains m observed bits; the mask itself is either fixed and shared or separately encoded. Correct partial-cue reconstruction needs separation of the *projected* prototypes, as proved in the reference model. Full-space separation alone does not suffice: two different patterns may agree on

every exposed coordinate. If their visible patterns are distinguishable beyond the observation noise, the identity can be selected and the missing coordinates completed from the retained model. The $d-m$ reconstructed bits were supplied by that model, not created from nothing. If a target index is also sent, charge its length and acknowledge that it may already solve selection without the partial cue. There is no universal fraction of visible bits guaranteeing recovery, and no claim that increasing load always forces that fraction monotonically to one. The study must report the cue, mask, model, residual and verification lengths together, and compare direct lookup and compressed checkpoints at the same fidelity. This retains the original worked example's purpose while removing a basin guarantee that the visible fraction alone cannot establish.
